Business Confidence and International Tourism Demand: Evidence from a Global Panel of Experts Valeria Croce *Received: 7 December 2015 Accepted: 2 January 2016 Published: 15 January 2016*

6 Abstract

In 2003, the United Nations agency for tourism (UNWTO), established a Panel of Tourism 7 Experts, to collect regular information on the short-term development of tourism. Experts? 8 opinions are since used to estimate a confidence index, which offers fairly accurate information 9 on the current and future development of the tourism sector worldwide and by macro-regions. 10 The significance of this instrument became evident during the 2008/2009 economic and 11 financial crisis, when indications about the impact and duration of the crisis were scarce, but 12 particularly relevant to a sector having experience virtually uninterrupted growth until then. 13 As the crisis unfolded, the constant revision of key explanatory variables of tourism demand, 14 such as GDP and inflation, jeopardized the accurateness of model-based forecasts, while soft 15 information collected through the Panel provided accurate indications about the evolution of 16 the crisis. This occurrence renewed interest in the value of such a simple, but effective 17 forecasting tool (Croce, Wöber et al. 2015, Croce 2016). 18

19

20 Index terms—current and future development of the tourism sector.

21 **1** Introduction

n 2003, the United Nations agency for tourism (UNWTO), established a Panel of Tourism Experts, to collect 22 regular information on the short-term development of tourism. Experts' opinions are since used to estimate a 23 confidence index, which offers fairly accurate information on the current and future development of the tourism 24 25 sector worldwide and by macro-regions. The significance of this instrument became evident during the 2008/2009 26 economic and financial crisis, when indications about the impact and duration of the crisis were scarce, but particularly This piece of research intends to achieve a better understanding of confidence index's contribution 27 to forecasting tourism demand. Following the approach proposed by Guizzardi and Stacchini (2015), this study 28 assesses the predictive power of the UNWTO Tourism Confidence Index-possibly the world's most widely used and 29 influential forecasts for the tourism sector-by factoring the index in structural time series models. Forecasts are 30 produced for the global scale, for advanced and emerging economies and five geographic macro-regions. Models' 31 performance is evaluated on in-and out-of-sample basis, and benchmarked against frequently used univariate 32 models. The index is first considered as stand-alone forecasting tool, with analyses focusing on its correlation 33 with series of actual values and assessing the accurateness of forecasts derived from the Index. A second part of 34 the analysis focuses on the Index value as explanatory variable in model-based forecasts, testing its usefulness as 35 predictor by factoring the index in structural time-series models. The predictive accuracy of augmented models 36 37 is eventually tested against simpler versions of structural models and autoregressive models. Results show that 38 information gathered through a simple and rather inexpensive tool

Author: e-mail: valeria.croce@gmail.com can be effective in improving the accurateness of shortterm forecasts of tourism demand.

Managerial implications of research findings are manifold. As demonstrated by Guizzardi and Stacchini (2015), tourism confidence indexes offer the possibility to obtain timely estimates of current and near-future levels of tourism demand. They hence represent a costeffective solution to compensate for the lag in official statistics publication. Previous research also proved that confidence indexes in general, and the UNWTO index in particular, have a good predictive power in identifying discrete turning points in the business cycle (Taylor
and ??cNabb 2007, Croce 2016), and can actively contribute to strengthen the resilience of a sector vulnerable
to changes in the external environment. The widespread use of the Internet and ICT developments further offer
unprecedented opportunities to leverage collective intelligence from large groups of individuals for forecasting
purposes (Segaran 2007), helping small businesses and budget-constrained destinations to embrace forecasting
practices, replicating processes which proved fruitful in other sectors (Wolfers and Zitzewitz 2004).

Furthermore, the data environment related to the tourism sector is characterised by lengthy statistical processes causing a dominating backward-looking approach ??Vanhove, 2005). The suboptimal availability of data, both in terms of scope and timeliness, coupled with a complex demand and supply, make a case for the use of confidence indexes in tourism, as they represent a cost effective methodology to forecast future changes in the development of the sector.

56 **2** II.

57 3 Literature Review

The view that confidence measures can predict fluctuations in economic series, such as the level of economic 58 activity or consumer spending, is a popular one in the economic literature. In the tourism-related literature, 59 60 instead, the use of confidence measures in forecasting is still a largely unexplored area ?? The existing literature on tourism forecasting is by far dominated by quantitative approaches, and only a I relevant to a sector 61 having experienced virtually uninterrupted growth until then. This piece of research intends to achieve a better 62 understanding of confidence index's contribution to forecasting tourism demand. Results confirm the tourism 63 confidence index as an effective method to improve the accuracy of forecasts. limited number of studies emphasize 64 the suitability of qualitative approaches to forecast tourism demand (for reviews, see Witt and Witt 1995, Goh 65 2004, Song and Li 2008, Goh and Law 2011, Peng, Song et al. 2014). In general, the use of subjective information 66 67 in forecasting -inter alia sentiment measures-is justified whenever quantitative indicators are missing, or their 68 provision is not sufficiently timely. Sentiment indexes are frequently considered as a valid source only when they compensate for the lack of "hard" information. In reality, these measures feature a number of properties 69 70 that make them useful indicators even in presence of quantitative information, such as the capability to factor non-measurable variables in estimates, and to provide a synthetic value of the impact these factors would have 71 on tourism development, and to provide near real-time forecasts (Guizzardi and Stacchini 2015). 72

The vast literature about forecasting provides clear directions about environment-specific conditions deter-73 mining which approach is the most suitable for a forecasting task. Wherever routine decisions are involved, 74 the assumption of continuity is realistic and sufficient quantitative information is available, the most complex 75 76 quantitative methods provide more accurate predictions than the simpler statistical methods ??Makridakis, 77 Wheelwright et al. 1998, Armstrong and. In areas such as physics and engineering, for instance, the accuracy of 78 causal and statistical forecasting models has achieved remarkable results in providing almost error free predictions (Makridakis and Taleb 2009). Whenever the conditions of the abovementioned requirements are non-optimal, a 79 80 combination of statistical methods and judgement proved to produce a more accurate forecast than each approach used separately (Goodwin 2002, Fildes, Goodwin et al. 2006, Fildes, Goodwin et al. 2009). 81

The kaleidoscopic and human-based nature of tourism poses serious threats to regular data collection and to the correct specifications of exogenous variables required by econometric models. Confidence indicators may offer a way out of this trade-off, as they incorporate in a single value the impact of many predictors, including 'those economic and market phenomena that are known but not quantified" (Caniato, Kalchschmidt et al. 2011).

86 The use of confidence indicators in forecasting is very popular in the general economic literature, but it is still 87 a rather unexplored research area in tourism. Swarbrooke and Horner (2001) first introduced this approach in the tourism literature, using business travellers' expectations about a foreign country's economic development to 88 forecast business travel flows. Njegovan (2005) used a probit model to examine whether leading indicators could be 89 used for the purpose of predicting short-term shifts in demand for business travel by air, to and from the UK. The 90 estimated probit model provided timely predictions of industry recessions and it was overall more accurate than 91 benchmark models. Allen and Yap (2011) examined whether a consumer confidence index could help predicting 92 Australian domestic tourism demand. Their findings suggest that the index has significant impacts in forecasting 93 VFR, but not other forms of tourism. Guizzardi and Stacchini (2015) provide evidence that information retrieved 94 from business surveys is effective in improving real-time forecasting of hotel arrival to regional level. Croce (2016) 95 found that prospects of UNWTO Panel of Tourism Experts can provide meaningful indications about the future 96 97 sign of international tourism demand growth, and that they can significantly contribute to improve forecasting 98 accuracy under specific circumstances.

This study intends to escalate the approach proposed by Guizzardi and Stacchini (2015) to the global and macro-regional level, using data provided by the UN agency for tourism, UNWTO. Following their design, Tourism Confidence Index prospects are factored in structural time series models and compared with forecasts produced by the same models, without the index. Forecasts are produced for the total number of international tourist arrivals, as well as for international arrivals to advanced and emerging economies and to five geographic macro-regions (see Figure 1). Models' performance is evaluated on in-and out-of-sample basis, and benchmarked against a baseline ARIMA model.

The choice of quantitative models is grounded in evidence Peng, Song et al. (2014) provide in their latest 106 attempt to generalise models' performance in forecasting tourism demand. Based on empirical findings of by-107 then published studies, their review confirms ARIMA processes as the most frequently used time-series approach, 108 109 but also highlights the advantages of structural time series models, when exogenous variables can be included (Gonzalez and Moral 1995, Kulendran and King 1997, Kulendran and Witt 2001, Turner and Witt 2001). 110 Structural time series models are based on the traditional decomposition of time series into trend, seasonal 111 and cycle components (Harvey 1990). This characteristic is expected to well capture evolutions of tourism 112 demand, especially in those macro-regions characterised by regular variations in their growth patterns. The strong 113 correlation of index values with international tourist arrivals, and the good fit of regression models including the 114 confidence index as predictor (Croce 2016), are also convincing about the positive contribution of the index in 115 improving forecasts. 116

III. 4 117

Data Characteristics 5 118

In this piece of research, UNWTO Tourism Confidence Index is used as input in regressive forecast models. 119 120 International tourist arrivals (ITA) are selected as dependent variables, and reflect the cross-border flow of people for tourism purposes. The following section describes the data used and illustrates those properties of 121 122 time series, which are a prerequisite for the selection of appropriate forecasting models.

6 a) International tourism development from 2003 to 2015, key 123 indicators 124

Since the early 1990s, UNWTO secretariat has been collecting series of international tourist arrivals from 125 126 destinations around the world, which are regularly published on the organisation's World Tourism Barometer. Despite methodological inconsistencies that characterize the production of tourism statistics, the information 127 128 provided by the UN agency can be deemed as the most reliable dataset covering virtually all world destinations, not last due to a compensation effect that characterizes large aggregates, as the eight series (see Figure 1) here 129 in exam. 130

Monthly growth rates in international tourist arrivals, compared to the same month in previous year, have 131 been calculated and aggregated in 4-month periods, in order to create time series consistent with the period 132 covered by confidence indexes. Each series consists of 38 observations, dating from 2003/2 to 2015/3 (see Figure 133 134 1). Of these, 26 observations have been used to estimate forecasting models' parameters for the first iteration, 135 and the remaining 12 observations are devoted to out-of-sample accuracy tests (shadowed area in Figure 1). the 136 out-of-sample period, although a pairwise test of means difference reveals no significant difference between the two sub-samples. 137

138 During the period in exam, international tourism has enjoyed growth in all world regions. Overall, international tourist arrivals grew on average by 4,5% each year, with typically regular variations around the long-term trend 139 (Standard Deviation(SD) = 3.87). Large variations were caused by external shocks of relevant magnitude, such 140 as the breakout of the SARS syndrome in 2003, and the 2008-2009 economic and financial crisis. In this period, 141 emerging economies typically grew faster (Means(M) = 5.61; SD = 5.02) than advanced ones (M = 3.64; SD =142 3.64), but these latter followed a more regular growth pattern, as indicated by a lower standard deviation. Mature 143 destinations such as Europe (M = 3.37; SD = 3.46) and the Americas (M = 4.22; SD = 4.64) are characterised by 144 145 a comparatively lower growth, largely explained by the already large volumes of international tourists attracted by these regions, and partly also by the distance from the most rapidly expanding outbound travel markets, 146 as China. Large volumes are also an indication that these regions host many established destinations, which 147 is reflected in regular growth patterns. Tourism demand for emerging destinations in Asia and the Pacific (M 148 = 7.24; SD = 10.00), the Middle East (M = 6.73; SD = 12.51) and Africa (M = 5.11; SD = 5.12) grew at a 149 faster pace, but also proved more volatile and vulnerable to external shocks. For all series bar the Middle East, 150 international tourism demand seems to grow more regularly during An augmented Dickey-Fuller test, performed 151 on the in-sample subset of data, depicts all series as nonstationary processes, with a confidence level of 99% 1 152 . First-order and second-order differencing returns stationary series with a type-I error probability lower than 153 1%. The aggregation in 4-month periods removes seasonality from arrival series, but a few series (Americas, Asia 154 Pacific and Europe) seem to feature a cyclical component. Growth rates pattern in these macro-regions could 155 be fit by a sinusoidal curve with cycles lasting approximately 3 years for Americas and Asia Pacific, and 6 to 7 156 157 years for Europe. Given the heavy weight destinations in Asia Pacific have in the emerging economies aggregate, 158 this series seems also to be characterised by a cyclical component with cycles of 3 years. reference. Changes are measured on a 5-step Likert (1932) interval scale, and collected by the means of an e-mail questionnaire. Experts 159 are asked to motivate their assessment mentioning the main determinants that underlie the expected evolution 160 of tourism demand. Waves are conducted three times a year and consist of a single round survey. Once a year, 161 evaluations and prospects for the full year are also collected. 162 (1)

163

8 FORECASTING MODELS

Since the second quarter of 2003, when the survey started, an average of 320 experts submit prospects and/or 164 evaluations each wave. Such a large basis of participating experts allows breaking down the index into 18 different 165 subsets, according to the level of economic development, the macro-region or the sector associated with the expert 166 (see Table ??). For most subsets of data, the average number of experts participating in each round exceeds 167 the threshold of 20 experts identified by Rowe and Wright (2001) as the optimal maximum number for Delphi 168 surveys (the italic font in Table ?? denotes those subsets which don't meet this criterion). All subsets are also 169 characterised by a relatively high deviation from the average index value, a positive factor in expert forecasting, 170 where forecast accuracy tends to increase with diversity of inputs (Gordon and Helmer 1964, Woundenberg 1991, 171 Williams and Webb 1994, Gupta and Clarke 1996, Rowe and Wright 1999). The average of all prospects collected 172 throughout the past 13 years is reported as indicator of the level of optimism (or pessimism) that distinguishes 173 each subset. 174

Table ??: Prospects of the UNWTO Panel of Tourism Experts (average value and standard deviation), average number of participants per round, and relationship with the correspondent series of international tourist arrivals (R and Granger test).

*: Diagnostics are related to the total number of ITA for sector subsets, and the correspondent series of ITA for all other subsets *: Significant at p<0.05; ***: significant at p<0.001

180 When considered as independent forecasting tool, prospects of the UNWTO Tourism Confidence Index show 181 a good fit with correspondent series of international tourist arrivals, as synthesised by R 2 values in Table ??. 182 Differences among subsets are largely explained by panel size, as the average number of experts participating in 183 the survey varies greatly across series and is strongly, and positively, correlated with R 2 where P is the index value at time t. Intercept ? and slope ? are estimated through a linear regression between the index and the 184 equivalent series of international tourist arrivals to return estimated growth values () at each time, hereafter 185 referred to as homologised TCI values. Series of homologised TCI values covering 4-month periods are used in 186 the analysis that follows. 187

The Tourism Confidence Index (TCI) is constructed using the un-weighted net balance of survey responses 188 collected through this survey, with 100 being the threshold value between contraction and expansion (see UNWTO 189 2016). In order to combine intra-year prospects and international tourist arrivals, index values have been 190 homologised by the means of a linear transformation as in (?? values (? = 0.72). Expectedly, R 2 values 191 are also inversely related to the accurateness of forecasts based on homologised prospects (? = -0.60). Series with 192 an R 2 of at least 0.50 are associated with a Mean Absolute Error (MAE) of 1.8 percentage points on average, 193 which goes up to 3.0 percentage points for series with a lower R 2 value. Expectedly, the index fits regular series 194 195 better than volatile ones.

This study argues that prospects can also be a valuable predictor of future tourism demand development, and they can significantly improve the accurateness of univariate forecasting models. On average, there is a positive elasticity between the index and international tourist arrivals growth. Based on (2), one percentage point change in arrivals growth corresponds to a change between 4 and 6 points in the index value. These values remain rather consistent for periods of positive and negative growth, and across geographical aggregates.

(2) 3 It must be noted, that the original definition of Granger causality does not account for latent confounding effects and does not capture nonlinear causal relationships.

In general, the test confirms prospects as a predictor that can significantly improve international tourist arrivals 203 forecasts (the test is significant for 13 out of 19 series). The null hypothesis that the lagged series (lag = 2) of 204 total prospects, as well as prospects provided by the Private Sector and Consultancy and Media experts, would 205 not be useful in predicting total international tourist arrivals' growth rates, can be rejected with a Type-I error 206 probability of 1%. The same hypothesis can be rejected for the lagged version (lag = 2) of prospects provided 207 by General Industry Bodies & Other, Local and Regional Destinations and Global Operators, although with 208 an error probability of 5%. Looking at aggregates by level of economic development and macro-regions, lagged 209 series of prospects (lag = 2) can be considered Granger-causing the correspondent series of international tourist 210 arrivals in Advanced economies, Americas and Europe, with a 95% confidence level. 211

It is appropriate to mention, that aggregates by level of economic development and regional series are marked 212 by a higher conceptual correspondence between series of actual values and series of prospects, than aggregates 213 by sector. While international tourist arrivals measure inbound flows to the country of destination, the survey 214 asks experts to estimate future developments in the tourism sector in their region and/or the business sector they 215 operate in. Prospects hence return estimates, which are not only conceptually broader than just the international 216 demand component, but which may also be strongly biased by local patterns, when provided by experts operating 217 in local businesses. Unsurprisingly, the stronger Granger-causality is observed in groups of experts operating in 218 global businesses. As such a discrepancy is lower for aggregates by economic development and macroregion, all 219 seven aggregates will be included in the forecasting exercise described below (bold font in Table ??). 220

²²¹ 7 IV.

222 8 Forecasting Models

The assessment of UNWTO Tourism Confidence Index contribution to improve forecast accuracy is based on a comparison of forecasts obtained with structural time series models, in which the index is factored, and structural models without the index as predictor. Forecasts based on simple autoregressive models are also computed, as baseline forecasts, as these models frequently outperformed more complex models in previous forecasting

227 competitions ??

²²⁸ 9 a) Baseline forecasts: auto-regressive moving-average models

For each series, different ARIMA models have been in order to select those who perform best in estimating one-229 step-ahead forecasts. The choice A Granger (1969) causality test has also been performed on series of prospects 230 and correspondent series of arrivals, to test the null hypothesis that prospects are exogenous with respect to 231 international tourist arrivals. If the hypothesis is rejected, it is likely that including past values of prospects in 232 the forecasting model would provide statistically more information than past values of arrivals alone. Granger 233 test values are also used to select those sub-sets of prospects (by the sector experts work for), which can be 234 useful in predicting values of international tourist arrivals at total level. Only those series with a significant 235 level of Granger-causality will be included in the analyses that follow. The test has been performed using the 236 'granger test' function available in 'lmtest' package R, the free software environment for statistical computing 237 and graphics. This function compares the unrestricted model -in which the dependent variable (y) is explained 238 by the lags (up to the specified order) of y and of the independent variable (x) -, and the restricted model -in 239 which y is only explained by the lags of y -by the means of a simple Wald test 240

241 **10 3**

242 . Results are reported in Table ??.

243 For each of the eight series in exam, forecasts have been obtained using packages in R. The 12 forecasts in the 244 out-of-sample dataset allow for a robust test of significance in forecast accuracy between baseline and competing 245 models. of models was updated each time a new observation was added, as in a real-life situation, where data arrive sequentially and in-sample dataset is updated accordingly, as new data become available. This function 246 available in R "forecast" package. The function uses a variation of the Hyndman and Khandakar algorithm, 247 which performs repeated KPSS tests to set the order of differencing (d), a stepwise search based on AICc values 248 to set the number of auto-regressive terms (p) and lagged forecast errors (q), and maximum likelihood estimation 249 (MLE) to identify the best fitting ARIMA model 4 250

In general, ARIMA forecasts show a low out-ofsample fit (R 2) with series of actual values, which is . Model parameters and diagnostics are reported in Table ??. 4 For more information see: https://www.otexts.org/fpp/8/7. Table ??: ARIMA models, parameters estimates and accuracy measures by macro-regions.

²⁵⁴ 11 b) Structural time series models

For each of the eight series in exam, forecasts have been estimated for a one-year horizon (three periods). As for the baseline forecasts, the process has been replicated for all 12 periods of the out-of-sample data. Structural time series models were estimated using R 'stsm', 'dlm' and 'KFKSDS' packages. The 'stsm' package offers the opportunity to apply five different models. Different models have been tested on each of the series, and the best performing model, in terms of in-sample MAE, has been retained for comparison with competing models.

The decomposition of each time series into its components generates small improvements in forecasts accuracy 260 for five of the eight series in exam (Table ??). Accuracy gains are measured as percentage increments compared 261 to corresponding baseline forecasts. The magnitude of accuracy gains is rather limited, as it falls between a 262 minimum of 15% and a maximum of 29% of the respective ARIMA Mean absolute error. Considerable accuracy 263 gains are observed for series with large movements around the trend, such as Asia Pacific (accuracy gains of 24 264 265 p.p. compared to the MAE of baseline forecasts) and Middle East (gains of 15 p.p.), but also for series with stable growth patterns, such as the series advanced economies (29 p.p.) and total (17 p.p.). A common reflected 266 in mean absolute error (MAE) values exceeding one percentage point (p.p.) for virtually all series. The only 267 exception is the moving average model of order one, used to forecast international tourist arrivals to Africa, with 268 an R 2 value of 0.77. This is reflected in comparatively accurate forecasts (MAE = 1.86), given the highly varying 269 pattern that characterises this series. As predictable, ARIMA models perform best with regular series. The auto 270 regressive model of order two, applied to total growth in international arrivals, stands out as the best performing 271 model, with an average error and standard deviation both below the one percentage point threshold. 272

Structural time series models are a flexible approach for time series analysis. They can be considered as statespace models for time series, based on a decomposition of the series into their unobserved, latent components, namely trend, cycle and seasonality. These models are frequently used not only to provide a description of the salient features of time series, but also to forecast their future values (Holden, Peel et al. 1990). The characteristic of modelling time series components well suits to forecast the series in exam, as the cyclical component, observed in some of them does not appear explicitly in the definition and selection of ARIMA models.

process was routinised by the use of the 'auto.arima' characteristic of these series is the regularity of their behaviour, being they regular in their cyclical growth pattern 6 6 Based on the longer in-sample dataset, tourist arrivals growth to the Middle East are not characterised by a cyclical component, but the 12 observations in the out-of-sample data a synusoydal type of pattern.

, or being they near-stationary series.

0 : all values refer to the first iteration of the model with 26 observations. *: Significant at p<0.05; ***: significant at p<0.01 Table ??: Structural time series models, parameters estimates and accuracy measures by macro-regions.

Structural time series models tend to reduce the variance of absolute errors; hence they contribute to make 287 288 predictions more robust. This improvement is particularly remarkable for the series Middle East, improved fit between forecasts and actual values, as expressed by R 2 values. Compared to baseline forecasts, structural 289 models return smoother cyclical fluctuations and a positive trend, which better fits the actual development of 290 tourism in these regions. Minor improvements in R 2 can be indeed observed for all series, with the exception of 291 Africa and Americas. A closer comparison of these two approaches reveals that structural time series models are 292 more effective in capturing turning points, while moving average and auto-regressive models more nicely match 293 the pace of growth before and after these points (see Figure 2). 294

²⁹⁵ 12 c) Augmented structural time series models

Homologised values of Tourism Confidence Index prospects (see section 3.b) were eventually factored in the 296 structural models used in the previous analysis. Both original series of homologised prospects and lagged versions 297 thereof have been added to the models, for a comparison of the best performing models. Seasonally differenced 298 series (lag = 3) of homologised prospects stand out as the regressors, which provide the most valuable inputs to 299 compound forecasts across all series. The only exception is the series emerging economies, for which original series 300 of homologised prospects have been used. Parameter estimates and accuracy measures are reported in Table ??. 301 For all other aggregates, accuracy gains brought by the Index range between negligible values (e.g. for the series 302 total the MAE is only 7%, or 0.03 p.p., below the non-augmented version) to a maximum of one-third of the 303 benchmark forecast error (or -2.1 p.p. for the Middle East, and -0.7 p.p. for Americas). Data plotted in Figure 1 304 305 provide explanation for these differences. In general, information contained in the index helps improving turning points and smoothening the amplitude of cyclical variations. While the nonaugmented version models, more 306 or less efficiently, regular variations in time series, the index introduces those changes that enhance the match 307 with observed values. This confirms Guizzardi and Stacchini's (2015: 219) conclusions that a confidence index 308 can be usefully exploited to explain deviations from trend-cycle, due to short-term shocks. This is symptomatic 309 of experts' capability to infer behaviour from the past, but also factor current inputs in their estimates, and 310 deliver a realistic version of future tourism developments. The use of the Index further reduces deviations from 311 mean errors over the 12 out -of-sample observations. advanced economies, the use of the index doesn't bring any 312 substantial change in forecast accuracy, although the Granger test (performed on the subset of data) pointed to 313 a possible contribution. This is likely explained by the uncertainty that lingered among tourism experts during 314 the period 2012/2 until 2014/2, especially those in Europe -where most advanced economies are-Crises of various 315 natures, primarily the European debt crisis, the risk of Grexit and the Crimea crisis, dragged experts' prospects 316 down. In fact, tourism demand proved to be more resilient than experts expected and negative factors were 317 more than offset by the rebound of important outbound travel markets, aggressive price policies as well as a 318 favorable economic environment and plummeting oil prices. When applied to emerging economies, the Index 319 instead slightly deteriorates the quality of forecasts (0.77 p.p. less accurate). This can be explained by the 320 diversity in tourism development that can be observed within emerging economies worldwide. The large size of 321 UNWTO Expert group allows the analysis of different subsets of the index by sector. Prospects, provided by 322 experts from five different tourism-related sectors, have been used as predictors of growth in international tourist 323 arrivals worldwide. Parameter estimates and accuracy measures are reported in Table 5 and forecasts plotted in 324 Figure 3. 325

The analysis doesn't point to professional experience in a specific sector as relevant to improve forecasts for the overall tourism sector.

13 Comparing Predictive Accuracy

Accuracy gains are eventually tested on out-of-The predictive accuracy of augmented models is reported in 329 Table ??. The test suggests that the use of the index returns significantly more accurate forecasts for three 330 series, namely Africa, Americas and Middle East. This is a noteworthy result from an operational viewpoint, as 331 forecasts for series with very high variations, such as Africa and Middle East, are frequently exposed to large errors. 332 Differences in forecast accuracy between the simpler version of structural models and ARIMA models appear 333 not to be significant, based on the Diebold-Mariano test. STS models for the series Middle East and advanced 334 335 economies, augmented with the index, become statistics computed on out-of-sample absolute errors. The use of 336 this test is a standard practice to compare the predictive accuracy of independent forecasts, and is particularly 337 suited to compare the accuracy of modelfree forecasts, as for instance survey-based forecasts. Furthermore, the 338 Diebold-Mariano test accommodates for a number of series characteristics, among which the presence of serially correlated forecast errors (see ??iebold & Mariano, 1995: 10). When used with short forecast horizons, as it 339 is the case here, forecast errors correlation can lead to particularly conservative results of the DM test, with 340 the null hypothesis being rejected too often. This may explain the limited number of statistically significant 341 results, and encourages the interpretation of significant errors as solid recommendations about the validity of 342 the correspondent forecasting approach. 7 The DM test has been chosen as measure of significance due to the 343

non-zero mean and serially correlated nature of forecast error series. Empirical applications of the test suggest 344 that on small samples the test can have the wrong size and reject the null hypothesis too often. For this purpose, 345 confidence levels start at 0.1. statistically more accurate than their ARIMA counterpart, with a type-I error 346 probability of 5%. sample values using the Diebold-Mariano (1995) 7 For all other series, results are encouraging, 347 348 but not significant from a statistical viewpoint. In particular, the use of the index from different sectors as predictor in STS methods seems to reduce the predictive power of models. This is explained by the conceptual 349 discrepancy between the prospects and actual series. While international tourist arrivals measure inbound travel 350 flows, UNWTO prospects capture changes in the overall tourism sector, including domestic demand. The related 351 index returns a measurement of the overall business climate rather than just its demand component, which may 352 partly explain the lack of significant results for some of the series. 353

Another caveat, strictly intertwined with this aspect, is that international tourism demand is typically proxied 354 by visitor arrivals, or overnights, at a destination. In spite of a remarkable progress, statistics on international 355 flows are still largely not comparable as based on a host of different methodologies, hence falling short of the 356 rigorous international comparability that would be required. Depending on the methodology, international tourist 357 arrivals may be close to the official definition of a visitor, namely a person, who travels to a place outside her usual 358 environment for personal or business/professional purposes, or may just monitor a subset of it, as for instance 359 360 visitors staying at hotels and similar establishments. This lack of homogeneity is also believed to introduce a 361 bias in results.

Another caveat stems from the use of a nominal group technique approach to collect prospects. This approach, appreciable for its simplicity, overlooks some of the techniques introduced to limit bias. Among them, it is worth mentioning the lack of multiple rounds, neglecting experts the opportunity to retrace their evaluation process based on group feedback, and the lack of feedback on their performance, which further limits their chances to

366 learn from past experiences.

367 14 Conclusions

For the varied nature of its demand, and the composite nature of supply, the analysis of tourism requires a complex system of indicators (Candela and Figini 2012), for which structured and comparable data are seldom available. Monitoring such a complex system of determinants is difficult and expensive (Vanhove 2011), and it is often not a priority of the many governments, who don't consider tourism a strategic asset for their economies.

The tourism sector is therefore one of those domains, where the use of qualitative forecasts is most promising,

373 (Vanhove 2011).

The general forecasting literature provides evidence that qualitative forecasting methods are particularly valuable in generating accurate indications on the future values of phenomena, which are otherwise impossible or difficult to measure (Helmer and Rescher 1959). Among these methods, confidence surveys are a convenient and simple method to implement, and can effectively contribute to provide fairly accurate estimates of key statistical indicators, Internet and ICT developments further offer unprecedented opportunities to spread the use of this technique, and involve large numbers of individuals in collaborative tasks at reasonable costs (Segaran 2007), which is already a popular approach in finance (see for instance Wolfers and Zitzewitz 2004).

The analysis presented in this report adds strong evidence of the informative power of confidence surveys in producing short-term forecasts of tourism demand, across different tourism regions. The confidence index proves particularly efficient to improve forecast accuracy for destinations, whose irregular growth patterns can be hardly fit by purely statistical models. The index also contributes to increase the accuracy of forecasts for destinations with stable growth patterns. The use of the index also contributes to reduce error variance, thus making the outcome of forecasting exercises more robust.

These results have important managerial implications. The main challenges faced by tourism analysts and forecasters stem from problems related to data availability, such as the incidence of missing information, the lack of consistent data series, the need of a rather complex set of indicators explaining tourists' behaviour (Frechtling 2001). Volatility of demand, and the sensitivity of demand to external events such as war, terrorism and catastrophes, further complicates the matter and limits the performance of quantitative methods commonly used in other sectors of the economy. Due to the lack of adequate information to model and forecast tourism demand, the proposed approach certainly proves a convenient alternative to fill this gap.

The tourism confidence index is here confirmed as an effective method to obtain reasonably accurate forecasts. A simple method, bearing limited costs for organisations, the use of confidence indexes in the tourism sector should be strongly supported. A broader use of this approach indeed would not only lead to a substantial improvement of insights intelligence available to policy makers and private operators, at any level, but it would
